

DIMENSIONING SYSTEM

BACKGROUND OF THE INVENTION

This application is a continuation of Application No. 08/918,196, filed August 25, 1997; which is a continuation of 5 Application No. 08/459,342, filed on June 2, 1995, now U.S. Patent 5,661,561.

Field of the Invention

The present invention relates to an apparatus for determining the dimensions of an object. More particularly, it relates to a dimensioning apparatus for determining the minimum size box necessary to enclose an object. Most particularly, the invention is directed to an automatic dimensioning system which accurately determines the dimensions of an object on a moving conveyor for package sorting and handling applications.

Description of the Prior Art

In order to reduce costs and increase the volume of packages handled, the shipping industry has pressed automated package handling. This has been accomplished through automated package identification by bar code labeling and automated sortation by 20 scanners identifying the labels and routing the packages. Package sorting is typically done based on the package size. In the shipping industry, shipping fees are directly related to the package size, weight and shipping destination. Determining the

correct package size in an efficient manner is therefore especially significant for both throughput and fee calculation.

While some progress has been made to provide automated systems for creating a three dimensional rendering of the package, the known systems are both complex and costly. There are several known systems for obtaining package dimensions. One system, shown in U.S. patent 5,193,120, utilizes a light source which projects collimated lines of light onto the object to be measured. An imaging system, utilizing a video camera, views the object at an angle with respect to the structured light so that the profile of the object can be visualized. The video signal is processed to calculate the three dimensional rendering of the object based on the lines of light.

Another system, shown in International Publication Number WO 94/27166, uses a laser beam which is reflected in a fan shaped form and directed using mirrors to a flat surface. The laser beam is oscillated at a high frequency where the difference in phase between the originating beam and the reflected light off of the surface of an object yields the height of the object. The system calculates the time it takes for the light beam to travel to and from the object. The system is mounted in a moveable carriage which passes over the object and after a multiplicity of height measurements determines the dimensions of the object.

U.S. Patent No. 4,758,093 discloses a three-dimensional measurement system which uses a holographic scanning mechanism. Triangulation based upon the projector to camera and relative

angles provides the foundation for computing the surface coordinates.

An apparatus which determines an object's height is shown in U.S. Patent 4,929,843. This system utilizes a laser beam which is 5 rastered across a conveyor surface creating a light stripe. A television camera, having a defined field of view, views the object at an angle causing the apparent location of the light stripe to move based on the object height.

Although the known systems can be used to obtain an object's height or to provide a three dimensional rendering, both systems view the object area at an angle, then produce a large analog video signal which must be filtered and processed. In order to increase the efficiency and reduce the cost of a dimensioning system, it is desirable to have a low cost, automated means for providing an accurate, high speed rendering of an article as it is carried on a conveyor. This object can be accomplished by reducing the amount of visual data processed.

SUMMARY OF THE INVENTION

The present invention provides a dimensioning system for 20 determining the minimum size box necessary to enclose an object traveling on a moving conveyor. The dimensioning system is comprised of a light source which generates a scan beam that is moved by a mirrored wheel. A line scan camera whose field of view is also moved by the mirrored wheel receives images of the scan

beam and outputs a serial analog waveform which is processed to compute a three dimensional box structure of the scanned object. Further processing is necessary for those objects that have complex curves.

5 It is an object of the invention to provide a dimensioning system which scans a three dimensional object on a moving conveyor belt and calculates a box capable of enclosing the object.

Other objects and advantages of the system will become apparent to those skilled in the art after reading the detailed description of a presently preferred embodiment.

BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 is a perspective view of a dimensioning system in position above a conveyor;

Figure 2 is a section view along line 2-2 in **Figure 1**;

Figure 3 is a view along line 3-3 in **Figure 1**;

Figure 4 is a view along line 4-4 in **Figure 1**;

Figure 5 is an explanatory diagram which indicates how the offset distance is measured and the height of the object is calculated;

20 **Figure 6** is a block diagram of the system;

Figure 7 is a flow chart of the enclosing process;

Figure 8A is an illustration of how the enclosing process determines the first four points;

Figure 8B is an illustration of how the enclosing process determines the second four points;

5 **Figure 8C** is an illustration of how the enclosing process boxes a box structure;

Figure 8D is an illustration of the examine objects phase;

Figure 9 is a perspective view of an alternative embodiment of the dimensioning system; and

Figure 10 is a perspective view of a second alternative embodiment of the dimensioning system.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The preferred embodiment will be described with reference to the drawing figures where like numerals represent like elements throughout.

A dimensioning system **15** in accordance with the present invention is shown in **Figure 1**. The dimensioning system **15** is positioned above a conveyor section **12** carrying an object **14**. The dimensioning system **15** is comprised of a main unit **10** and a parabolic reflecting surface **26**. The dimensioning system is mounted on a stand **16** above a conveyor section **12** carrying an object **14**. The main unit **10** is enclosed in a housing **18** which is made by conventional means of sheet metal or molded plastic. Only

a portion of the housing **18** is illustrated in order to show the components of the dimensioning system **15** contained therein.

The dimensioning system **15** is comprised of a laser diode and lens assembly **20** mounted in the housing **18**. The laser assembly **20** produces a coherent, collimated beam **21** which is directed toward a six-sided, multi-faceted mirrored wheel **22**. The mirrored wheel **22** is driven by a motor **24**, which moves the beam **21** as it is reflected from the turning mirrored wheel **22**. This produces a series of continuous beams, which have been graphically represented by **21a**, **21b** and **21c**. The series of beams **21a**, **21b** and **21c** are directed toward a high quality, parabolic reflecting surface **26** which reflects the series of beams **21a**, **21b** and **21c** to produce a scan of the conveyor belt surface **13** normal to the direction of travel.

As graphically illustrated in **Figure 4**, the parabolic surface **26** is used to produce parallel beams **21a'**, **21b'**, and **21c'** from the mirrored wheel **22** and direct them onto the conveyor belt **13**. The mirrored wheel **22** is located at the focus of the parabolic reflecting surface **26**. If the laser beam **21** is moved directly from the mirrored wheel **22** to the belt **13**, the scan beams would radiate from a point source and cast shadows from adjacent objects onto each other. By making the scan beams parallel from above, no shadowing occurs.

In the preferred embodiment, the laser diode/lens assembly is a Mitsubishi 35mW, 690nm laser diode with an aspheric glass lens

having a 6.24mm focal length. Referring back to **Figure 1**, the motor **24** and the motor control circuitry **25** is designed to minimize motor drift. In the preferred embodiment, the motor speed is constantly 533 rpm.

5 A CCD (charged coupled device) line scan camera **30** is mounted in the housing **18** and directed toward the mirrored wheel **22**. The camera **30** has a line field of view **42**. As the mirrored wheel **22** turns, the line field of view **42** is directed to corresponding positions (represented as **42a**, **42b** and **42c**) with the series of scan beams **21a**, **21b** and **21c**. The camera **30** outputs a serial analog signal to the logic processor **35** mounted in the housing **18**.

The mounting geometry of the laser assembly **20**, camera **30**, mirrored wheel **22** and parabolic reflecting surface **26** is shown in detail in **Figures 2-4**. The laser assembly **20** and the camera **30** are mounted on a plane which is parallel to the axis of the mirrored wheel **22**. As shown in **Figure 3**, the laser assembly **20** and the camera **30** are offset from each other by an angle θ which is approximately 5° . θ is defined by measuring the angle between the laser beam center **21** and the central axis **44** of the field of view **42** of the camera **30**.

20 As shown in **Figures 2** and **4**, the mirrored wheel **22** sweeps the laser beam **21** across the parabolic reflecting surface **26**, with approximately 90° of the swept beam **21** striking the parabolic

reflecting surface **26**. The parabolic surface **26** reflects the laser beam **21** to provide a series of parallel beams **21a'**, **21b'** and **21c'**.

The camera field of view **42** is aligned in the same plane as the laser beam **21** and is directed at the mirrored wheel **22**. As shown in **Figure 2**, the central axis **44** of the field of view **42** is reflected by the parabolic reflecting surface **26** to be approximately normal to the conveyor surface. The angle of the parallel laser beam **21'** after reflecting off of the parabolic surface **26**, remains θ from the central axis **44** of the camera field of view **42**.

The object height **14** at a given point is measured by triangulation using the angle θ . The offset angle θ between the laser beam **21'** and the normal camera view field **42** above the conveyor creates a horizontal offset d between intercept point **40a** where the laser beam normally intercepts the conveyor surface and image point **40b** when the laser beam **21** strikes an object **14**. As shown in **Figure 5**, the offset d is captured by the linear view field **42** of the camera **30**. When the intercept point **40a** and the image point **40b** are the same, i.e. when no object is present, the image is oriented to fall at one end of the CCD linear array d_0 . As an object comes under the scan beam **21**, the image point **40b** moves toward the other end of the CCD array based on the object height at that discrete point on the conveyor belt. The

calculation of offset d , the distance from d_0 , is explained in more detail hereinafter.

The output of the camera 30 is fed to the input of the A/D (analog to digital) converter 32 as shown in **Figure 6**. The A/D output is a binary digital pulse corresponding to the position of the laser spot.

In the preferred embodiment, the line scan camera 30 is a Dalsa model CL-C3. The lens has a focal length of 170mm. To maintain focus over a 914.4mm (36 inch) depth of field, the CCD array is tilted at an angle in relation to the median plane through the lens. The angle of tilt is determined using the Scheimpflug condition. The angle is dependent on the focal length of the lens and the plane angle of the object. The plane angle of the object is projected towards the lens. The median plane of the lens is extended to intersect the object plane's extended line. The image plane's line is similarly extended to intersect at the same point. For the three lines to intersect, the image plane must be angled. The angle that causes the three extended lines to intersect is the Scheimpflug angle. The angular relationship is achieved by the spacial relationship and orientation between the object on the conveyor, the reflected light path, and lens and CCD array. The CCD array must then be slightly offset such that the object sample points are imaged onto the active area of the CCD array. The use of the Scheimpflug condition allows for a smaller reflected laser

spot size over the entire depth of field. This yields increased resolution.

The CCD array contains 512 pixels. The maximum scan height is 914.4mm (36 inches), which yields a resolution of 1.778mm (0.07 inch) per pixel. The camera **30** takes between 28 and 55 microseconds to integrate and clock out the pixels after integration. 28 microseconds is the minimum amount of time to clock out the signal.

The camera control circuitry consists of a pixel clock and a cycle clock. The cycle clock controls the integration time and the pixel clock controls the rate at which the pixels are clocked out. The cycle clock is synchronized with the scans such that it pulses 240 times (per scan) as it moves across the conveyor belt surface (at 6.35mm (0.25 inch) increments) starting at scan zero (the conveyor belt edge). The pixel clock is synchronized with the A/D converter to admit the serial data stream.

A block diagram of the dimensioning system **15** is shown in **Figure 6**. The components required to output parallel light and to receive the return light have been described above.

After the camera **30** receives the return light, the CCD light-sensitive pixels accumulate a charge proportional to the intensity of the exposure. The output is an analog waveform where the voltage is proportional to the intensity of return light. The

laser spot can be modeled with a Gaussian distribution. It is then input to the processor **35**.

The processor **35** is comprised of an A/D converter **32** which accepts the analog signal from the camera **30** and outputs a digital signal. The converter uses a fixed level comparator circuit to digitize the analog waveform from the camera **30**. In the first stage of the A/D process, the incoming signal is filtered from unwanted noise and amplified. The following stages provide variable gain. The final section performs the A/D conversion which produces a binary output pulse.

The logic board **34** accepts the binary signal from the A/D converter **32**. The signal is a single pulse corresponding to the reflected image point detected by the CCD array in the camera **30**. When the LVAL output from the scanner is set high (a signal that indicates the camera is clocking out its pixels) the leading edge is used as a starting point to measure the distance to the laser spot pulse. Two 12 bit, 60 MHz counters are started at the rising edge of the LVAL signal. The first counter is stopped and stored in memory at the leading edge of the laser spot pulse indicating the laser beam image point **40b**, and the second counter is stopped and stored in memory at the falling edge of the signal. The processor **35** calculates the difference between the edge values and this represents the center of the laser beam image point **40b**. This number is converted to a distance d that the laser image point **40b**

is apart from the conveyor intercept point **40a** d_0 . Using this distance d and the angle θ , the box height is calculated.

The height h is calculated by the logic board **34** using the simple trigonometric relationship:

5

$$h = \frac{d}{\tan \theta} .$$

(Eqn. 1)

This relationship can be grouped with the conversion of the counters to a distance in one step. By doing this for each point, the center count can be converted directly to a height. By creating a lookup table, any variation between units in processing can be calibrated out.

Each time d is measured, the height h is calculated at that discrete point. Measurements of the beam image points are taken as the scan progresses across the conveyor **12** at preferably 0.25 inch intervals. This yields 240 discrete sample image points per scan. A tachometer **37**, measures the conveyor belt speed, and based on the scan frequency, the distance between scans is calculated.

Each sample image point is composed of an x,y,z component. The x component is the distance, in discrete 0.0625 inch increments, obtained from counting the tachometer pulses. The y component is the distance, in discrete 0.25 inch increments, from the scan zero side of the conveyor. The z component is the object height h , in 0.0625 inch increments, from the belt towards the

parabolic reflecting surface as measured by the laser-camera interaction.

As shown in the flow diagram of **Figure 7**, once the data is acquired (**step 50**), it is processed to define a box structure.

5 After a scan has been completed, the data from the 240 sample points are fed into a preprocessor function (**step 51**) in the software. The purpose of the preprocessor is to convert the raw height data from the camera into .07 inch increments, and to remove calibrated aberrations from the data. For example, if sample image point number 5 is always 2 counts larger than the average, the data contained in sample 5 will be lowered by 2 counts.

Once the preprocessor has normalized the data, it is fed into a run-length encoder module (**step 52**). The run-length encoder takes the 240 discrete height samples and converts the entire scan into multiple line segments. Line segments are constructed from groups of adjacent sample image points with similar non-zero heights that lie on the same scan line. Each line segment is defined by its starting position on the conveyor belt, length, and height. Line segments are no longer discrete, their components are averages of the discrete points they were built from. As shown in the flow diagram, after the data is acquired, and preprocessed, the line segments are then passed to the collection phase. During the data collection phase, the incoming line segments are assigned to

a particular box structure according to their position to the previously gathered line segments.

During the collection phase (**step 53**) individual line segments may contain information for more than one object. If the data for the second object is apparent due to trends in the previously gathered data, the line segment will be broken into two line segments and assigned normally. If the line segment cannot be broken it will be assigned normally to the closest matching box structure, therefore this box structure will now contain the information for more than one object, the split phase (**step 54**), and examine object phase (**step 64**) should remove this extra information later on.

If during a particular data collection period a box structure did not receive at least one single line segment, indicating the absence of the object in the current scan line, that box structure is passed to the split phase.

During the split phase (**step 54**), the software examines the outer edges of the image defined by the box structure. If the split module notices drastic changes in the slope of line segments contained in the box structure, the module will break the box structure down into multiple box structures. Each of these box structures will contain tag information to rebuild the original box structure if the slopes were misinterpreted. All of this data will then pass to the data-reduction-unit.

During the data reduction unit phase (**step 56**), all line segments that do not touch the edges of the calculated box structure image are deleted. This is accomplished by deleting any line segment where the end points do not touch or exceed the 5 previous or next scan line segment's end points. This decreases the processing time during the enclosing phase.

The enclosing phase (**step 58**) encloses the imaged object within the smallest box structure. To enclose the object, the angular orientation of a first side must be determined and then two perpendicular sides and an opposing parallel side are calculated such that the area within is minimized and contains all of the line segments. In order to determine the angular orientation of a first side, points are defined from the line segment data comprising the box structure.

As shown in **Figure 8A**, the *T* point is the beginning of the first line segment in the box structure, and has the minimum *x* value. The *B* point is the end of the last line segment, and has the maximum *x* value. The *R* point is the beginning of the line segment closest to the scan zero point, *i.e.* the minimum *y* value. 20 The *L* point is the end of the line segment farthest from scan zero, *i.e.* the maximum *y* value.

After these four points, *T, R, B, and L*, are determined, line segments are computed. For reference, the center of the box

structure is taken as the point midway between the maximum and minimum x and y values.

As shown in **Figure 8B**, the line segments \overline{TR} , \overline{RB} , \overline{BL} , and \overline{LT} are moved tangentially away from the center until they enclose all of the individual line segments defining the box structure. The last sample point where each of the computed tangential lines touch a line segment of the box structure defines four new points; TR , RB , BL and LT .

The final part of the enclosing phase involves defining 16 lines, each having its own angular orientation, by the eight points. The first area is comprised of 8 lines defined between each adjacent point, T and TR , TR and R , R and RB , etc. The second eight lines are defined between every other point, TR and RB , RB and BL , BL and LT , etc. and T and R , R and B , B and L , etc.

Each of the computed lines defines an angle with respect to the conveyor width and running length. For example with respect to the line defined by points BL and L as shown in **Figure 8C**, an exaggerated line A is computed parallel to line BL to L , and is moved in from outside of the box structure until it contacts a sample point. Line B is computed parallel to line A and is moved in from the side opposite A . Two additional lines normal to lines A , B are computed, C , D and are moved in to box the box structure. This

operation is performed for each of the sixteen lines computed above. The smallest area computed that encloses the box structure is output to the next phase.

A check is performed by calculating the area of the box structure based on all of the edge points and the area within the lines defining a box. If the two areas are approximately equal (step 59), the box is then closed, otherwise the box is sent to a reprocessing phase.

During the reprocessing phase (step 60) any extraneous line segments that are not similar (step 62) to the adjacent segments are adjusted until they match adjacent data. The box structure is then passed back to the enclosing phase. If the box structure has been through the reprocessing phase previously, it passes to the examine object phase.

The examine object phase (step 64) examines the data and recreates a silhouette picture of the object(s) that were scanned. As shown in Figure 8D, box structures reaching this phase are of irregularly shaped objects, objects touching other objects or objects oriented in such a fashion that the standard process could not accurately enclose them. This phase of the process allows for proper enclosure of tires and separates complex arrangements of touching objects.

The examine object phase (step 64) of the method generates outlines of the box structures and examines these outlines looking

for corners. Concave corners and corners that indent into the box structures are noted. The corners are connected to form sides of boxes, and matching concave corners are connected to split apart multiple box structures where they meet. The new, individual box structures are then enclosed within the smallest rectangle possible.

5 The final step of the process is the close phase (**step 66**) where the box data is displayed and transmitted to a peripheral device.

It will be recognized to those of ordinary skill in the art that the enclosing process can be tailored to specific applications where known parameters exist. For example, where it is known that only rectangular box-shaped objects will be scanned, the comparison done in **step 59** can be made based on a higher approximation of equality since the area of the box structure based on all of the edge points should nearly equal the area of the lines defining the box. Additionally, if it is known that all items being scanned have a uniform height, but different items may have a significantly different height, the split phase **step 54** may be configured to look 20 for variations in the uniformity of line segment height as one way to determine the existence of two box structures occurring within the same set of scans.

The software also corrects for offsets in the mirrored wheel facets and for changes in the measured height which are caused by

the uneven distances between the mirrored wheel and the surface of the conveyor. As shown in **Figure 4**, the scan beam length **21a** is greater than the scan beam length **21b**. This difference in length follows a simple trigonometric relationship which is programmed 5 into the software.

The memory on the logic board **34** is large enough to store the relevant data and some of the frequently used program code. In the preferred embodiment, there are four 256K X 32 SRAM modules on board. A preferred processor for implementing the software is a Texas Instruments TMS320C30 CMOS digital signal processing integrated circuit.

An error count is kept to log the number of times a sample had to be eliminated because of multiple transitions. The quality of the measurement is also recorded. A scale from 1 to 99 indicates the confidence level that the dimensions are accurate. If there is any doubt about the dimensions, it will be assigned a lower number. This number can be used as a threshold to determine whether the dimensions are accurate enough to be used for billing.

While the preferred embodiment utilizes a parabolic reflecting 20 surface **26**, an alternative embodiment could use a transmission hologram **126** to collimate the laser beam as shown in **Figure 9**. A Fresnel lens could also be used to collimate and refract the individual laser beams in a scan to be approximately parallel to one another.

It is also possible to replace the parabolic reflecting surface **26** with two flat mirrors to approximate a parallel scan. The scan is divided into three parts. The central portion is a direct scan from the mirrored wheel toward the central portion of 5 the conveyor. Because the width of the central portion is limited, shadowing is minimized. The other two portions of the scan will cover the outer portions of the conveyor. Two flat mirrors are angled above the rotating mirrored wheel. The light travels upwards to the mirror and is then reflected down to the conveyor in a near parallel scan. The flat mirrors are approximating the outer regions of a parabola, with the center portion being replaced by a direct scan from the mirrored wheel. This arrangement requires the software to be more complex to correct for the distance and angle changes caused by the additional mirrors and the divided scan.

It is also possible to replace the parabolic surface **26** with a multi-faceted parabolic surface to approximate a parallel scan. The scan is divided into discrete parts. The light travels upwards to the mirror segments and then is reflected down to the conveyor in a near parallel scan. The mirror facets are approximating a 20 true parabolic surface. This arrangement requires the software to be more complex to correct for the distance and angle changes caused by the additional mirrors. In this alternative embodiment, 479 samples are acquired per scan.

If there is no possibility that more than one object will be present during scanning, no reflecting surface is required. As shown in **Figure 10**, the main unit **10** may be used solo with no reduction in accuracy. With only one object under the system at a time, no shadowing can occur. In this situation parallel scanning is unnecessary and the raw, angular scan becomes the preferred embodiment. No external optics are needed and system cost and size can be reduced.

While the preferred embodiment uses a line scan camera, an alternative embodiment could use a PSD (position-sensitive detector). The PSD outputs a current which is relative to where the reflected laser spot is detected. The processing of the output is simplified since the output current relates position without having coefficient luminance information present.

While the present invention has been described in terms of the preferred embodiment, other variations which are within the scope of the invention as outlined in the claims below will be apparent to those skilled in the art.
